

# Recursive Median Filters for Time-Varying Graph Signal Denoising

David B. Tay

School of Information Technology, Deakin University, Australia

Graph Signal Processing Workshop 2023

# Introduction

- Graph Signal Processing (GSP): leverages pair-wise relationship between nodes of a graph (irregular domain) to formulate operators on data/feature/signal defined over the nodes.
- Most existing graph signal operators in the literature are linear and deal with time static signals. Consider time-varying signals here.
- Nonlinear operators, such as the median, is known to out perform linear operators in traditional signal processing, especially for images.
- Propose recursive graph median filters for time-varying signals.
- Application to denoising real world sensor network data where Gaussian noise and impulse noise are simultaneous present in the data.

## Previous works

- S. Segarra, A. G. Marques, G. R. Arce, and A. Ribeiro, "Design of weighted median graph filters," in *2017 IEEE CAMSAP*.

First proposals for graph median filters for time static signals. Application to denoising not considered.

- D. B. Tay and J. Jiang, "Time-Varying Graph Signal Denoising via Median Filters," in *IEEE Trans on Cct. and Sys. II*, March 2021.

Nonrecursive graph median filters for time-varying signals. Application to denoising with Gaussian or impulse noise, but not simultaneously.

# Motivation

- Wireless sensor networks (WSN) for environmental monitoring: cheap sensors typically have limited computational and communication resources.
- Sensors often operate in a harsh environment: measurements can be subjected to significant levels of noise.
- Gaussian noise: from thermal sources and from limitations of the cheap sensor hardware.
- Impulsive noise: models external interferences, e.g. electromagnetic, and intermittent sensor failures.
- Both types of noise will be simultaneously present, especially in harsh environments.

- A graph  $G \equiv (V, E)$  consist of vertices  $V$  and edges  $E$ . Vertices usually indexed as  $1, \dots, N = |V|$ .
- Adjacency matrix  $\mathbf{A} = [a_{i,j}]$  contain weight of edges. No connection:  $a_{i,j} = 0$ . Usually  $\mathbf{A}$  is sparse.
- Diagonal matrix  $\mathbf{D} \equiv \text{diag}(d_i)$  where  $d_i = \sum_j a_{i,j}$  is the degree.
- Graph Laplacians:  $\mathbf{L} \equiv \mathbf{D} - \mathbf{A}$ ,  $\mathbf{L}_S \equiv \mathbf{D}^{-1/2}\mathbf{L}\mathbf{D}^{-1/2}$ ,  $\mathbf{L}_R \equiv \mathbf{D}^{-1}\mathbf{L}$ .
- Graph signal  $f : V \rightarrow \mathbb{R}$  represented as vector  $\mathbf{f} = [f(1) \dots f(N)]^T$ .  $f(i)$  represent the signal/feature value at node  $i$ .
- Linear graph signal operator:  $\mathbf{f}_{out} = \mathbf{H}\mathbf{f}$ .
- An important class of linear operators are polynomial functions of the Laplacian  $h(\mathbf{L})$ : can be implemented distributively and has localization property.

# Example of graph filter

Denoising using Tikhonov regularization:

- Have a noisy version of a graph signal  $\mathbf{y}$  from an underlying noiseless version  $\mathbf{f}$ .
- Solve

$$\min_{\hat{\mathbf{f}}} \left( \|\hat{\mathbf{f}} - \mathbf{y}\|^2 + \frac{\gamma}{2} \hat{\mathbf{f}}^T \mathbf{L} \hat{\mathbf{f}} \right)$$

- Closed form solution  $\hat{\mathbf{f}} = \mathbf{H}_{opt} \mathbf{y}$ , where the linear operator is

$$\mathbf{H}_{opt} = \left( \mathbf{1} + \frac{\gamma}{2} \mathbf{L} \right)^{-1}$$

- This is equivalent to a smoothing (low-pass) filter and in practice a polynomial approximation is used. The simplest is first order given by

$$\mathbf{H}_{opt,approx} = \mathbf{1} - \frac{\gamma}{2} \mathbf{L}$$

which is 1-hop localized.

# Time-varying graph signal

- A function  $f(i, t)$  of both the vertex  $i$  and time  $t$ .
- When  $i$  is fixed, we have a regular time signal and when  $t$  is fixed, we have a static graph signal.
- Matrix representation

$$\mathbf{F} = [\mathbf{f}_1 | \mathbf{f}_2 | \cdots | \mathbf{f}_T]$$

where  $T$  is the number of time instants and the column vectors  $\mathbf{f}_k$  ( $k = 1, \dots, T$ ) represent the graph signal at time instant  $t = k$ .

# Time-vertex graphs

- To capture correlation across time and vertex, product graphs, from two underlying graphs, are used.
- First underlying graph with adjacency  $\mathbf{A}_G$  models the pair-wise relationship between (sensor) nodes.
- Second underlying graph is an undirected line graph which models the time correlation with the adjacency (size  $T \times T$ ) given by

$$\mathbf{A}_T = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 & 0 \\ 1 & 0 & 1 & \cdots & 0 & 0 \\ 0 & 1 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 & 0 \end{bmatrix}$$

## Time-vertex graph (cont.)

- Define adjacency of  $K$ -hop graph.

$$\mathbf{A}_{G,K} = \left( \left( \sum_{k=1}^K \mathbf{A}_G^k \right) \succ \mathbf{0}_N \right) - \mathbf{I}_N$$

direct connection of all nodes (sensors) that are  $K$ -hops away, denoted as  $\mathcal{N}_G(i, K)$ .

- Strong product graph:

$$\mathbf{A}_{SP} = \mathbf{I}_T \otimes \mathbf{A}_{G,K} + \mathbf{A}_T \otimes (\mathbf{A}_{G,K} + \mathbf{I}_N)$$

- Each row (or column) of the product graph adjacency corresponds to a unique combination of (sensor) node  $i$  and time instant  $t$ . The pair  $(i, t)$  is known as a *time-vertex node*.

# Correlation structure

- 1 The adjacency  $\mathbf{A}_{SP}$  defines the set of nodes whose signal values are correlated:

$$\mathcal{N}_{SP}(i, t; K) = \mathcal{N}_t^1(i) \cup \mathcal{N}_t^2(i) \cup \mathcal{N}_t^3(i) \cup \mathcal{N}_t^-(i) \cup \mathcal{N}_t^*(i) \cup \mathcal{N}_t^+(i)$$

Partitioning into disjoint subsets.

- 2 Single centre time-vertex nodes at different times:

$$\mathcal{N}_t^1(i) \equiv \{(i, t - 1)\}; \quad \mathcal{N}_t^2(i) \equiv \{(i, t)\}; \quad \mathcal{N}_t^3(i) \equiv \{(i, t + 1)\}$$

- 3 Neighbourhood time-vertex nodes at different time instants:

$$\mathcal{N}_t^-(i) \equiv \{(j, t - 1) : j \in \mathcal{N}_G(i, K)\}$$

$$\mathcal{N}_t^*(i) \equiv \{(j, t) : j \in \mathcal{N}_G(i, K)\}$$

$$\mathcal{N}_t^+(i) \equiv \{(j, t + 1) : j \in \mathcal{N}_G(i, K)\}$$

# Median time-vertex filter

- Median operator on a set of  $L$  numerical values  $\mathcal{F} = \{f_1, f_2, \dots, f_L\}$ :

$$\Gamma(\mathcal{F}) \equiv \tilde{\mathbf{f}}_{rank} \equiv [\tilde{f}_1 \ \tilde{f}_2 \ \dots \ \tilde{f}_L]; \quad \text{MED}(\mathcal{F}) \equiv \frac{1}{2}(\tilde{f}_{\lfloor (L+1)/2 \rfloor} + \tilde{f}_{\lfloor L/2 \rfloor + 1})$$

- When  $L$  is odd, the median gives the middle value.
- Sometimes need to repeat the values to give more weight, e.g. if  $P = 2$ ,

$$P \diamond \{-1, 1, 3, 3\} = \{-1, -1, 1, 1, 3, 3, 3, 3\}$$

- Notation:  $f(\mathcal{N}_t^*)$  denote the set of signal values over the set of nodes  $\mathcal{N}_t^*$ .

## Median time-vertex filter (cont.)

Let  $f(i, t)$  and  $y(i, t)$  denote the input and output. The filter operates sequentially from time  $t = 1$  till  $t = T$  as follows:

- 1 When  $t = 1$ , the output is given by:

$$y(i, 1) = \text{MED} (P \diamond f(\mathcal{N}^2 \cup \mathcal{N}^3) \cup f(\mathcal{N}^* \cup \mathcal{N}^+))$$

- 2 For  $t = 2, \dots, T - 1$ , the output is given by:

$$y(i, t) = \text{MED} (P \diamond (y(\mathcal{N}^1) \cup f(\mathcal{N}^2 \cup \mathcal{N}^3)) \cup y(\mathcal{N}^-) \cup f(\mathcal{N}^* \cup \mathcal{N}^+))$$

- 3 When  $t = T$ , the output is given by:

$$y(i, T) = \text{MED} (P \diamond (y(\mathcal{N}^1) \cup f(\mathcal{N}^2)) \cup y(\mathcal{N}^-) \cup f(\mathcal{N}^*))$$

**PREVIOUS DENOISED VALUES ARE USED IN DENOISING CURRENT VALUES, I.E. RECURSIVE.**

# Noise model

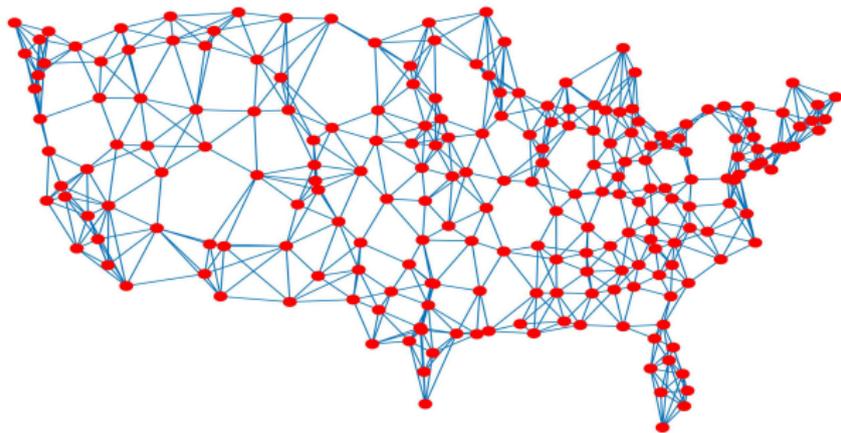

$$f(i, t) = \begin{cases} x_{min} & \text{with probability } d/2 \\ x(i, t) + n & \text{with probability } 1 - d \\ x_{max} & \text{with probability } d/2 \end{cases} \quad (1)$$

- $n$  has a Gaussian distribution with zero mean and variance  $\sigma^2$ .
- $d$  is the probability (percentage) of corruption due to impulsive noise.
- $x_{min}$  ( $x_{max}$ ) is the minimum (maximum) value of the noiseless signal  $x(i, t)$ .

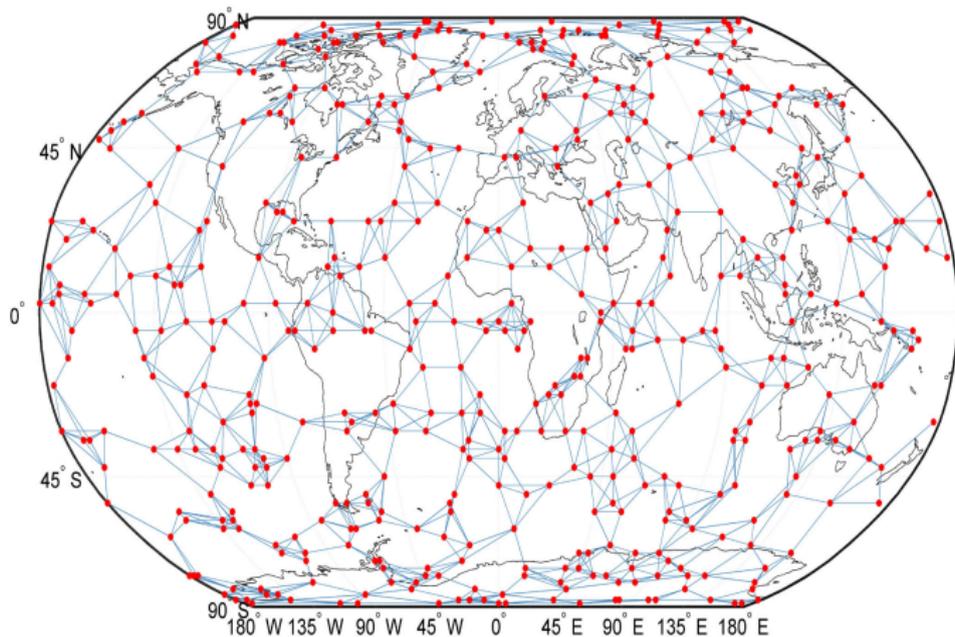

# Experiments

- Use real world sensor measurements from three sources.
- Corrupted simultaneously by Gaussian noise and impulsive noise
- Compare with non-recursive median filter and linear filter.
- Found that the simplest filter with with  $K = 1$  (1-hop) and  $P = 1$  (no weighting) generally gives the best results.
- Many results but will only show a representative.

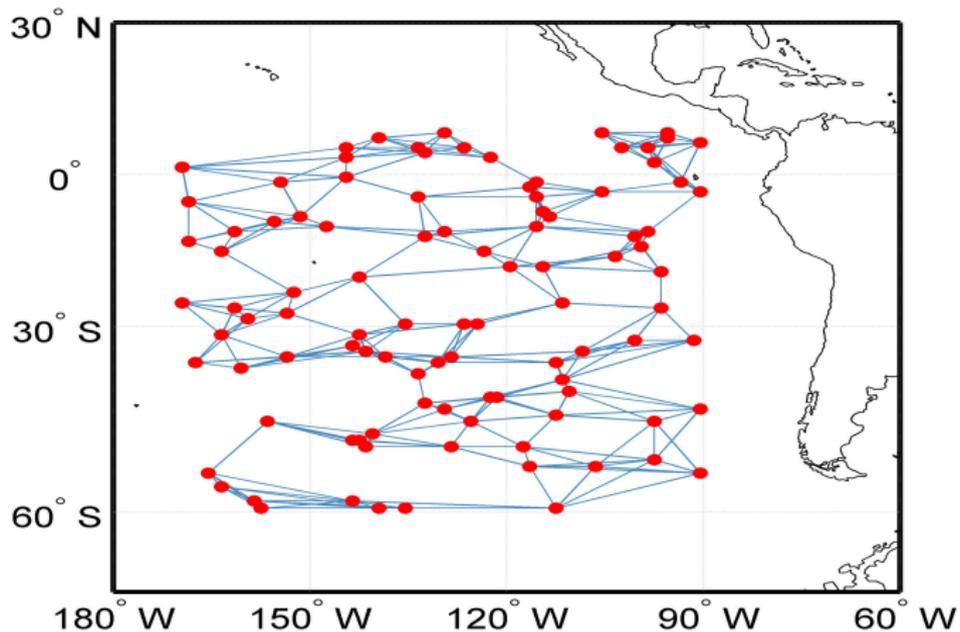

# US temperature graph

# Global sea-pressure graph

# Pacific ocean sea-temperature graph

# Results

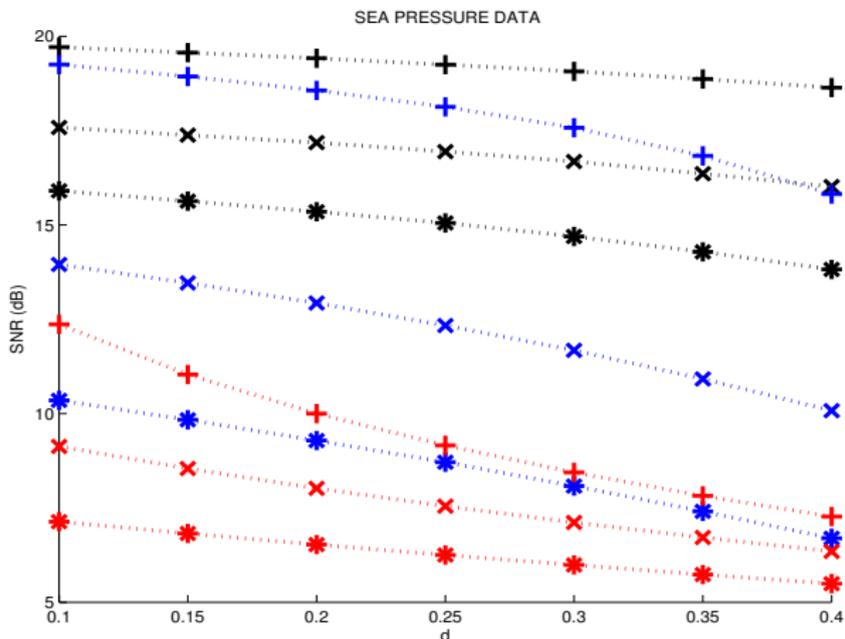

Figure: Black: REC<sub>SP</sub> Blue: NMED<sub>SP</sub>, Red: LIN<sub>SP</sub>. Three different  $\sigma$  values for Gaussian noise. '+' :  $\sigma = 0.1$ , 'x' :  $\sigma = 0.25$ , '\*' :  $\sigma = 0.4$ . The horizontal axis  $d$  is the % corruption with impulsive noise.

# Results

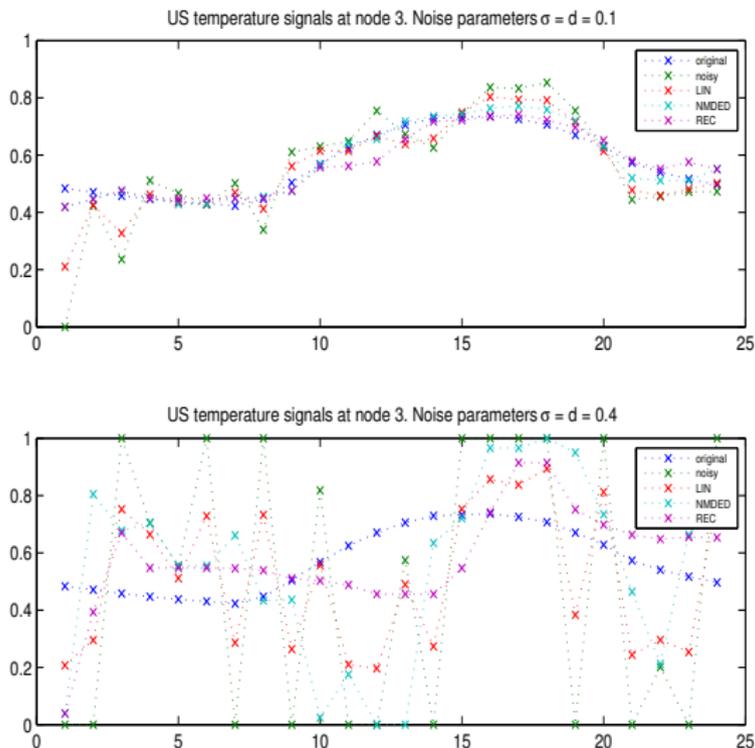

Figure: Various time signals of US temperature data at node 3.

# Conclusions

- Efficient time-vertex median filters have been proposed for denoising time-varying graph signals.
- Filters can be implemented distributively using only information from immediate neighbours: suitable for resource limited sensor nodes.
- Performance tested and compared with the linear counterpart, under varying noise levels.
- Median filters superior and sometimes better by a large margin in high levels of noise situations.
